Abstract

Objective: To investigate whether measuring pancreas volume with abdominal tomography in patients with severe abdominal pain can predict acute pancreatitis.

Method: The case-control study was conducted at Adnan Menderes University from January 1, 2015, to January 1, 2017, and comprised patients who were diagnosed with acute pancreatitis. Pancreas volume measurements of patients and control group were made with Telemed Ekinoks software using freehand technique. Presence of a correlation between pancreas volume and pancreatitis was found in patients aged <57 and a cut-off value was calculated for pancreatitis in this particular patient group.

Results: Of the 183 subjects, 132(72%) were patients with a mean age of 59.6±16.5 years, and 51(28%) were controls with a mean age of 55.8±18.6 years (p=0.170). The difference between the groups in terms of pancreas volume was significant (p<0.001). There was a negative correlation between age and pancreas
volume among the patients (p<0.001), the correlation was not significant among
the controls (p=0.898). Among the subjects aged <57 years, the cut-off value was
calculated at 95.055, and sensitivity to pancreas volume was 70.91% while
specificity was 82.14%. Positive predictive value was 88.6%.

Conclusion: High pancreas volume with pancreatitis was observed in patients
aged <57 years.

Key Words: Abdominal pain, Pancreatitis, Pancreas volume, Computed
tomography.

Introduction

Acute pancreatitis (AP) is a severe inflammation of the pancreas with sudden
onset of serious abdominal pain and a high rate of resulting morbidity and
mortality. Although the aetiology is not exactly known, it is most often associated
with gallbladder stones and alcohol.1 AP is also associated with intra-acinar
activation of proteolytic enzymes, leukocyte chemo attraction, release of
cytokines and oxidative stress.2-4 The common effect on in all these pathways is
inflammation extreme response.

The human pancreas is a small, soft organ intertwined with the bowels, stomach,
spleen and visceral fat. AP must be confirmed by a thorough in vivo volumetric
pancreas evaluation. So far, pancreatic volume (PV) evaluation studies have been
limited to autopsies and computed tomography (CT) studies, which require the
use of X ray.5 Only a handful of magnetic resonance imaging (MRI) examinations
have been published6-8, but none were valid. Previous studies in humans,
however, have demonstrated that PV changes are consistent with age and the
development of metabolic diseases.5,9,10

All major CT companies are developing volume-based softwares with high
prices. Many countries in the world cannot afford these expensive softwares. The
major problem of these softwares is that calculations must be done in CT portals,
and not on personal computers (PCs). The current study was planned to suggest
an affordable and practical software for measuring PV in an effort to speed up the
diagnosis of pancreatitis.

Patients and Methods
The case-control study was conducted at Adnan Menderes University from
January 1, 2015, to January 1, 2017, and comprised AP patients. After approval
from the institutional ethics committee, patients admitted to the emergency room
(ER) due to severe abdominal pain were evaluated with CT with the following
specifications: axial slices, W/L: 400/40, kVp/mA: 120/50, slice
thickness/increment: 3/1.5mm, pitch: 0.75, scan range: 1 cm above the diaphragm
to the end of the pelvis, contrast injection parameters: automatic triggering,
increased flow >5 mL/min, high iodine concentration >300 iodium/mL,
suspended respiration. Patients included had at least two of the three stated
conditions: acute abdominal pain and tenderness suggestive of pancreatitis; ultra-
sonography (USG) and/or CT suggestive of AP; and serum amylase/lipase ≥3
times the normal value.\(^1\)

Patients with a history of pancreatic malignancy and surgery, and those with
diabetes mellitus (DM) were excluded.
Pancreas volume was measured using the abdominal CT pancreatitis
classification was made using the Balthazar method\(^11\), which is a routine method.
PV measurements were made by free-hand technique with Ekinoks (Telemed-
Ekinoks Software, Bogazici University Technopark, Istanbul, Turkey, version
1.7, 2017) advanced CT and MRI imaging workstation software. Abscess and
necrosis areas were excluded from the measurements. Patients’ serum C-reactive
protein (CRP) and lipase levels were recorded.

For statistical analysis, normality of continuous variables was examined using the
Kolmogorov-Smirnov test. Descriptive statistics of normally distributed variables
were expressed as mean ± standard deviation (SD) and sample t-test was used for
comparison between the groups. Descriptive statistics of non-normally
distributed variables were shown as median (25-75%), and the Mann-Whitney test was used for comparison between the groups. Since age and PV indicated normal distribution, the correlation between them was studied using Pearson’s correlation coefficient. Because CRP was non-normally distributed, the correlation between CRP and PV was examined using Spearman’s correlation coefficient. Chi-square automatic interaction detection (CHAID) was used to determine the factors affecting PV in the patient group. Data was compared between the control and the patient groups. According to CHAID analysis, the PV cut-off value was calculated to determine patient grouping based on age <57 years. Receiver operating characteristic (ROC) curve analysis was used to determine the power of PV in distinguishing the patient and control groups. P<0.05 was considered statistically significant.

Results

Of the 183 subjects, 132(72%) were patients with a mean age of 59.6±16.5 years, and 51(28%) were controls with a mean age of 55.8±18.6 years (p=0.170). There were 80(60.6%) women in the patients group, and 29(56.9%) in the control group (p=0.646). PV was 98.7±36.8 in the patients group and 79.6±26.0 in the control group (p<0.001) (Table 1; Figure 1).

There was a significant correlation between age and PV in the patient group (r=-0.322, p<0.001), but no significant difference was found in this regard in the control group (r=-0.018 p=0.898).

PV was 114.2±36.6 mL in patients aged 57 years and less, and 87.7±33.0 mL in those aged over 57 years (p<0.001) (Figure 2).

There was a negative correlation in patients aged >57 years and the control group (r=-0.236, p=0.039; r=-0.579; p=0.004, respectively), but no significant correlation was found between age and PV in patients aged <57 years and the control group (r=0.073, p=0.596; r=0.147, p=0.454, respectively).
There was no correlation between the Balthazar grade and volume in patients aged >57 years ($r=-0.089$, $p=0.441$), while a significant correlation was found in patients aged <57 years ($r=0.329$, $p=0.014$).

CRP level was significantly higher in patients aged <57 years (43.0 (range: 14–138) than in the control group 3.5 (2–6.5) ($p<0.001$). A significant correlation was observed between CRP and PV ($r=0.352$, $p=0.008$). There was a significant difference in the patients group according to the PV cut-off value as the CRP level was 18 (range: 3.8–50.5) in patients with PV $\leq$95.05mL, and 66mL (range: 24–153) in patients with PV >95.05mL.

According to ROC analysis, when the PV cut-off value was 95.055mL, sensitivity was 70.91% (95% confidence interval [CI]: 57.1–82.4) and specificity was 82.14% (95% CI: 63.1–93.9) (Figure 3). The positive likelihood ratio (+LR) was 3.97 (95% CI: 1.8–8.9), and the negative likelihood ratio (-LR) was 0.35 (95% CI: 0.2–0.6).

Positive predictive value (PPV) was 88.6% (n=39) and negative predictive value (NPV) was 59% (n=23).

Discussion

The study found a correlation between age and PV which decreased with the age of the patients compared to the control group, and when PVS were classified according to age, the PV of patients was 98.7±36.8 with a statistical finding of 57 years.

Prognosis of AP changes with the severity of the disease. Approximately 75–80% of the cases progress mildly and can be improved only with intravenous (IV) fluid therapy and supportive care. The remaining cases show progression with mortality and serious complications by 30–50%. Therefore, early diagnosis of the disease and determination of therapeutic strategy depending on the severity of the disease is of paramount importance. Various scoring systems are used in order to determine the severity of the disease. However, none of these scoring systems can determine the severity within the first hour of the presentation. Easy-
to-use and inexpensive indices that will determine the severity of the disease and
give information about the prognosis within a few minutes are needed. We
believe that PV measurement from abdominal CTs performed in ER on patients
with abdominal pain and suspected of AP would be helpful both in ruling out the
other diagnoses and the initiation of early treatment.
The results reported in literature are controversial in terms of the correlation
between PV and age. Meieret al.\textsuperscript{10} stated that “some publications report a
significant inverse correlation between pancreatic volume and age in healthy
individuals, while others do not report such as correlation”. In the past, PV
measurements have been made mostly using autopsies or retrospective CT
screening that involves radioactive agents.\textsuperscript{14} These studies found PV to be
72.4±25.8mL and 79.2±24.1mL in healthy adults aged 20-60 years.\textsuperscript{15} In the
present study, PV was 79.6±26.0mL in patients aged 18-95 years. Although a
decrease was observed in PV in the control group with age, no statistically
significant correlation was observed.

Contrast-enhanced abdominal CT (CECT) has an important place in the diagnosis
of pancreatitis and the determination of severity, and it has been involved in the
Pancreatic Diagnosis Criteria.\textsuperscript{1} In a prospective study on this topic, CECT of 202
patients was evaluated and specificity rates were reported as 92% and 100%.\textsuperscript{16} In
1985, Balthazar et al. developed an assessment system known as Balthazar
classification, which is based on a general assessment of the dimensions, contour
and density of the gland and peri-pancreatic anomalies in prediction of the
severity of the disease.\textsuperscript{17} In 1990, Balthazar validated the CT severity index of
acute pancreatitis by combining the original grading system he developed with
the presence and grade of pancreatic necrosis.\textsuperscript{18,19}

PV is known to increase in AP cases.\textsuperscript{20} In our study, consistent with the
literature\textsuperscript{20}, PV was higher in AP patients compared to the control group.
We found a moderate negative correlation between PV and age in patients aged
<57 years. According to the ROC analysis performed to examine the power of
PV to distinguish between patient and control subjects, when the cut-off value of the volume was 90.055, sensitivity was 70.91%, and specificity was 82.14%. The +LR value was 3.97, and the -LR was 0.35. PPV was 88.6%, and NPV was 59%

In the analysis made to determine presence of the correlation between PV and the severity of pancreatitis, a moderate positive correlation was found between the Balthazar score and PV in patients aged <57 years (p<0.001). While the Balthazar grade and CT severity index were increased, i.e. the severity of the disease was increased, PV was also found increased, suggesting that PV may be useful in the prediction of AP severity.

CRP is valuable in acute response, especially because of its short half-life\textsuperscript{21,22} and CRP is often used during admission and subsequent follow-up of AP patients. In our study, a moderate positive correlation was observed between CRP and PV in patients aged <57 years (p=0.008). This supports the findings that PV is also associated with the severity of the disease.

The current study has some limitations as it excluded patients with malignancy, pancreatic surgery and DM. Also, post-recovery control pancreas CT scan was not performed.

**Conclusion**

High PV with pancreatitis was observed in patients aged <57 years. The measurement of PV may be helpful for physicians in early diagnosis, determination of the severity of the disease, prognosis, therapy planning and referral of patients considered to be carrying AP risk.
